(54) Method and device for regeneration and relay of optical transmission signal and wavelength division multiplexing transmission system using the same

(57) Provided are a regeneration relay 2 which comprises a light receiver 5 for converting an inputted optical signal 10 to an electrical signal, thereby outputting the electrical signal 14; a light transmitter 6 for converting the electrical signal 14 outputted from the light receiver 5 to an optical signal, thereby outputting the optical signal while varying a wavelength of the optical signal; and a wavelength monitor 4 for controlling the light transmitter 6 so that a wavelength of a light outputted from the light transmitter 6 and a wavelength of a

light inputted to the light receiver are made to be equal to each other. Provided is an optical regeneration relay used in a wavelength multiplexing transmitting system, which is capable of relaying a regenerated light with a simple constitution and facilitating a control of a wavelength of a signal on a transmitting path by monitoring a wavelength of a first stage wavelength multiplexing unit for outputting a signal to the transmitting path.

Description

[0001] The present invention relates to a method for regeneration and relay of an optical transmission signal in a wavelength division multiplexing transmission system using an optical fiber and a signal regeneration relay using the wavelength division multiplexing transmission system.

[0002] In a wavelength division multiplexing transmission system which multiplexes a plurality of waves as a signal channel so as to transmit the multiplexed waves, a long haul transmission system using, for example, EDFA as relays, which transmits the signal channels by non-regeneration relay transmission, has been used. However, in the optical amplifying relays that performs a multi-stage long haul transmission, a distance within which a transmission is satisfactorily conducted is limited due to factors such as fiber chromatic dispersions in fiber transmission paths and a S/N deterioration in an optical fiber amplifier. In order to perform further long haul transmissions, electrical regeneration relaying has been required.

[0003] Schematically, conventional systems for the electrical regeneration relaying are the ones that receive an optical signal using a wavelength division multiplexing receiving terminal unit and converts an electrical signal to an optical signal again to transmit the optical signal using a wavelength division multiplexing transmission unit.

[0004] In the conventional wavelength division multiplexing transmission relaying including the optical regeneration relaying that has been performed in the wavelength division multiplexing transmission system, the transmission signal is sent out by a transmission terminal unit composed of a wavelength division multiplexing transmission unit and a wavelength division multiplexer for multiplexing a plurality of outputted lights from the wavelength division multiplexing transmission unit. The optical signal attenuated on the transmission path is amplified by an optical amplifying relay system composed of an optical fiber amplifier as it is, and further transmitted.

[0005] In an optical regeneration relay system, the transmission signal that has been subjected to the wavelength division multiplexing is demultiplexed by a wavelength division demultiplexer. The receiving terminal unit comprises a plurality of receivers equal to the demultiplexed wavelengths in number. In the receiving terminal unit, each signal is received to be subjected to an optical-to-electrical conversion. These signals are converted to optical signals with different wavelengths by optical transmitters, each of which is provided for corresponding one of the signals. The optical signals with the different wavelengths are multiplexed by the wavelength division multiplexer again, and sent out to a subsequent transmission system having transmission paths.

[0006] In the case of the foregoing regeneration relay

system, the wavelength division multiplexing transmission unit is provided for each regeneration relay. Then, an optical transmitter with a different wavelength for each channel must be used within the wavelength division multiplexing transmission unit. In the wavelength division multiplexing transmission unit for the regeneration relaying in each stage included in the transmission system, the wavelength of the optical signal outputted from the individual optical transmitter, which is built in the wavelength division multiplexing transmission unit, must be monitored strictly; so that the structure of the wavelength division multiplexing transmission unit is very complicated.

[0007] The present invention was made from the viewpoint of the problems which have been posed by the foregoing technologies inherently. The object of a method of a regeneration and relay of an optical transmission signal of the present invention and an optical regeneration relay of the present invention is to enable a regeneration relaying by a simple construction and to facilitate a control of a wavelength of an optical signal on a transmission path by monitoring the wavelength of the optical signal outputted from a first stage wavelength division multiplexing transmission unit to the transmission path.

[0008] The optical regeneration relay of the present invention comprises an optical receiver for converting an optical signal inputted thereto to an electrical signal, thereby outputting the electrical signal; an optical transmitter for converting the electrical signal from the optical receiver to an optical signal and allowing a wavelength of the optical signal to be variable, thereby outputting the optical signal with the variable wavelength; and a wavelength monitoring circuit for controlling the optical transmitter so that the wavelength of a light emitted from the optical transmitter and the wavelength of a light incident onto the optical receiver are equal to each other.

[0009] The above and other objects, features and advantages of the present invention will become more apparent from the following detailed description when taken in conjunction with the accompanying drawings wherein;

[0010] First, for the sake of a conventional optical relay will be described for facilitating the understanding of the present invention, prior to the description of a regeneration optical relay of the present invention.

[0011] Fig. 1 is a diagram showing a structure of a wavelength division multiplexing transmission system including a conventional regeneration optical relay system.

[0012] Fig. 1 exemplifies a block diagram showing an example of a structure of the conventional wavelength division multiplexing transmission relay including an optical regeneration relay in a wavelength division multiplexing transmitting system. A transmission signal is transmitted from an optical transmission terminal station system 500 composed of a wavelength division multiplexing transmission unit 101 and a wavelength division multiplexer 102 for multiplexing a plurality of output lights from the wavelength division multiplexing transmission unit 101. The optical signal attenuated on the transmission path 104 is amplified, while remaining unchanged as a light, by an optical amplifying relay system 600 composed of optical amplifiers 103. The amplified optical signal is further transmitted.

[0013] In an optical regeneration relaying system 700, the transmitted signal that has been subjected to the wavelength division multiplexing is demultiplexed by a wavelength division demultiplexer 105. A receiving ter-

minal station unit 110 comprises a plurality of receivers 111 equal to the wavelengths in number; which are to be demultiplexed. In the receiving terminal station unit 110, each of the demultiplexed signals is received by corresponding one of the receivers 111, and subjected to an optical-to-electrical conversion by corresponding one of the receivers 111. In a wavelength division multiplexing transmission unit 107, these signals are converted to optical signals with different wavelengths by corresponding optical transmitters, respectively. The optical signal with the different wavelengths are again multiplexed by an optical wavelength division multiplexer 108, and the multiplexed optical signal is transmitted to a subsequent stage transmitting system 800 having a transmission path 109, which is located in the subsequent stage.

[0014] In the case of the regeneration optical relay system as described above, the wavelength division multiplexing transmission unit is employed for each regeneration relay. Optical transmitter for transmitting optical signals with different wavelengths for each channel must be used in the wavelength division multiplexing transmission unit. The wavelengths of the optical signals outputted from optical transmitters built in the wavelength division multiplexing unit for the regeneration optical relay in each stage, which are included in the transmission systems, must be monitored, so that the structures of the optical transmitters are exceedingly complicated.

[0015] Next, the regeneration optical relay of the present invention will be described with reference to the drawings.

[0016] Fig. 2 is a diagram showing a structure of a first embodiment of the regeneration optical relay of the present invention.

[0017] The regeneration optical relay 2 shown in Fig. 2 is composed of an input side optical divider 3, a wavelength monitoring circuit 4, a light receiving circuit 5, a light transmitting circuit 6, and an output side optical divider 8. An optical signal input 10 with a specified wavelength from an optical fiber 1 is inputted to the regeneration optical relay 2. The optical signal outputted from the optical fiber 1 is branched into two optical signals by the optical divider 3. One of the optical signals obtained by branching the optical signal input 10 is inputted to the light receiving circuit 5 so as to be subjected to an optical-to-electrical conversion, and then transferred to the light transmitting circuit 6. The light transmitting circuit 6 performs an electrical-to-optical conversion based on the transmitting signal that has been subjected to the optical-to-electrical conversion, which is outputted from the light receiving circuit 5, so as to output an optical signal with a modulation wavelength identical to that of the optical signal input 10.

[0018] On the other hand, the other optical signal obtained by branching the optical signal input 10 by the optical divider 3 is inputted to the wavelength monitoring circuit 4. The wavelength monitoring circuit 4 compares

the wavelength of the optical signal input 10 from the optical divider 3 with that of an optical signal output 11 which is obtained by branching an output signal from the light transmitting circuit 6 via the optical divider 8, the optical signal output 11 being a part of the output signal, thereby monitoring the wavelength of the output signal outputted from the light transmitting circuit 6. The result obtained after comparing and monitoring the wavelengths of the optical signal input 10 and the optical signal output 11 is transmitted to the light transmitting circuit 6 as a wavelength control signal 9. The light transmitting circuit 6 that received the wavelength control signal 9 transmits a light with a wavelength as an optical signal output 11, which exhibits an identical wavelength to that of the optical signal inputted to the light receiving circuit 5.

[0019] Thus, in the wavelength division multiplexing transmitting system for processing signals, each signal being close to others in a value of a wavelength, the individual regulations of the wavelengths of the output signals from all of the regeneration optical relays, which are coupled to each other in the relay transmitting system, are automatically conducted by sufficiently controlling the wavelengths of the signals from the transmitting side terminal station.

[0020] In Fig. 2, the light receiving circuit 5 comprises an optical-to-electrical conversion circuit including a light receiving element. The regenerated electrical signal 14 obtained by performing the optical-to-electrical conversion for the optical signal input 10 is transmitted to the light transmitting circuit 6. The light receiving circuit 5 comprises a 3R function according to demand.

[0021] The light transmitting circuit 6 has a function to output a light with a wavelength controlled based on the wavelength control signal 9 which is outputted from the wavelength monitoring circuit 4, as well as a function to modulate the output light 15 from the light transmitting circuit 6 based on the regenerated electrical signal 14 from the light receiving circuit 5. The light receiving circuit 6 is a light source having a function capable of performing a high speed electrical-to-electrical conversion and outputting a signal with a variable wavelength.

[0022] The wavelength monitoring circuit 4 detects the difference between the wavelength of the optical signal input 10 and the wavelength of the branched optical signal output 13. The optical signal input 10 is inputted to the wavelength monitoring circuit 4 from the transmission path via the optical divider 3, and the branched optical signal output 13 is obtained by branching the optical output 15 from the light transmitting circuit 6 by the optical divider 8 and inputted to the wavelength monitoring circuit 4. For the detection of the wavelength difference, optical principles such as spectroscopy, interference and diffraction are utilized. Information relating to the wavelength difference is outputted to the light transmitting circuit 6 as the wavelength control signal 9.

[0023] Next, an operation of the regeneration optical

relay of Fig. 2 will be described.

[0024] First, when the demultiplexed optical signal input 10 is inputted to the regeneration optical relay 2 via the optical fiber 1, the optical signal inputted is branched in the optical divider 3, and then the branched signals are transmitted to the light receiving circuit 5 and the wavelength monitoring circuit 4, respectively. The optical signal inputted to the light receiving circuit 5 is subjected to the optical-to-electrical conversion therein, and outputted to the light transmitting circuit 6 as the regenerated electrical signal 14 that is an electrical signal.

[0025] The light transmitting circuit 6 modulates the optical output based on the electrical signal inputted thereto, and outputs the modulated signal as the optical signal. The optical signal outputted from the light transmitting circuit 6 is branched into the optical signal output 11 and the branched optical signal output 13 by the optical divider 8. The main signal is outputted from the transmission path via the optical fiber 7. On the other hand, the branched optical signal output 13 is fed-back to the wavelength monitoring circuit 4.

[0026] The wavelength monitoring circuit 4 detects the difference between the wavelength of the branched optical signal input 12 from the optical fiber 1 and the wavelength branched optical signal output 13 fed-back from the light transmitting circuit 6, and outputs the detection result to the light transmitting circuit 6 as the wavelength control signal 9. The wavelength monitoring circuit 4 controls the light transmitting circuit 6 by the wavelength control signal 9 so that the wavelength of the optical signal input 10 inputted to the regeneration optical relay 2 and the wavelength of the optical signal output 11 from the regeneration optical relay 2 will be equal to each other.

[0027] Next, a concrete circuit configuration of the wavelength monitoring circuit 4 will be described.

[0028] Fig. 3 is a diagram of a concrete configuration of a wavelength monitoring circuit 410 that is shown as the wavelength monitoring circuit 4 in Fig. 2. The wavelength monitoring circuit 410 comprises an optical switch 411, a wavelength variable filter 412, a light receiving element 413, a wavelength control signal generating circuit 414, and an optical switch/wavelength variable filter control circuit 415. The optical switch 411 is the one having two input terminals and one output terminal, which alternately switches two optical signals depending on time, which are the branched optical signal input 12 from the optical fiber 1 and the branched optical signal output 13 fed-back from the light transmitting circuit 6. The wavelength variable filter 412 sweeps the wavelength of the light from the optical switch 411. The optical output from the wavelength variable filter 412 is subjected to a photoelectric conversion by the light receiving element 413. For example, a rotary etalon plate, a sweep Fabriperot resonator and the like can be used as the sweep wavelength variable filter described above.

[0029] The wavelength control signal generating circuit 414 calculates the wavelength difference from the photoelectric conversion signal alternately switched depending on time, and transmits the wavelength control signal 9 to the light transmitting circuit 6 of Fig. 2. The optical switch/wavelength variable filter control circuit 415 controls the switching control signal of the optical switch 411, the wavelength sweep signal of the wavelength variable filter and the wavelength control signal generating circuit 414.

[0030] An operation of the wavelength monitoring circuit 410 shown in Fig. 3 will be described with reference to Figs. 4(a) to 4(c).

[0031] Figs. 4(a) to 4(c) are the diagrams showing the waveform changes of the control signal and output signal against time. Fig. 4(a) shows the switching control signal of the optical switch 411, Fig. 4(b) shows the wavelength sweep signal in the case where, for example, a rotary etalon plate is used as the wavelength variable filter 412, and Fig. 4(c) shows the photoelectric conversion output of the light receiving element 413.

[0032] As shown in Fig. 4(a), during the time region A the optical switch 411 is in a connection state where the optical switch 411 guides the branched optical input 12 to the wavelength variable filter 412. During the time region B the optical switch 411 is in a connection state where the optical switch 411 guides the branched optical output 13 to the wavelength variable filter 412. The optical switch 411 is controlled by the optical switch/wavelength variable filter control circuit 415 so that the optical switch 411 is alternately switched between these two connection states. In synchronization with the control signal for the optical switch 411, the wavelength variable filter 412 performs one sweep in each of the regions A and B as shown in Fig. 4(b).

[0033] The light after passing through the wavelength variable filter 412 constituted by a rotary etalon plate is converted to an electrical signal as described in Fig. 4(c) by the light receiving element 413. The rotary etalon plate rotates at a fixed speed.

[0034] An angle of the light incident onto the rotary etalon plate relative to the rotary etalon plate is changed by this rotation, with the result that a wavelength of the light transmitting through the rotary etalon plate changes. Accordingly, Fig. 4(c) shows the change of the wavelength of the transmitting light against the abscissa indicating time. If the wavelength of the light of the branched optical input 12 differs from the wavelength of the light of the branched optical output 13, which transmit through the rotary etalon plate, both of the lights transmitting through the rotary etalon plate show the peaks of the intensities in the different sweep timings, and the times t_1 and t_2 that are the periods from the start of the sweep to the appearance of the peaks differ from each other. The wavelength control signal generating circuit 414 calculates the difference between the times t_1 and t_2 , and transmits the control signal as the wavelength control signal 9 to the light transmitting

circuit 6.

[0035] The above descriptions were made for the case where the rotary etalon plate and the sweep type Fabry-perot resonator which make the mechanical sweep are used as the wavelength variable filter 412. An acousto-optic tunable filter (AOTF) that is an electronic wavelength variable filter may be used as the wavelength variable filter 412, which has recently enhanced its characteristics. The AOTF has realized a wavelength selection characteristic of a waveguide mode inter-coupling of light travelling along an optical waveguide by utilizing a diffraction effect of a surface acoustic wave which propagates along the optical waveguide. In this case, a frequency of a high frequency sine wave signal supplied to a piezoelectric transducer, which drives the surface acoustic wave, is swept, so that it is possible to sweep the wavelength of the transmitting light similarly to the mechanical sweep. The wavelength monitoring circuit can also be structured using the acoustic optic tunable filter.

[0036] Although the description for the wavelength monitoring circuit in which the wavelength discriminating function that is a principal component is constituted by the wavelength variable filter was made, a spectroscopy may also be used as a component that can utilize the wavelength discriminating function.

[0037] Next, a different embodiment of the wavelength monitoring circuit 4 will be described.

[0038] Fig. 5 is a diagram showing a structure of another embodiment of the wavelength monitoring circuit 4 which uses the combination of an arrayed-waveguide grating (hereinafter referred to as a AWG) and an array photodiode (hereinafter referred to as an array PD), which has been developed as a spectroscopy, especially as a high integrated spectroscopy with a small size.

[0039] In the AWG, lights simultaneously incident onto a plurality of waveguide arrays undergo the phase delay after passing therethrough. Each of the waveguide arrays has a gradually different length from others and the phase delay changes in proportion to the length of the waveguide. The AWG utilizes the fact that an inclination angle of a wavefront, which is produced after the passage of the light through the waveguide array, varies depending on the wavelength. Specifically, the AWG is an integrated type spectroscopy having the structure that a principle of the spectroscopy using the plane-shaped reflection diffraction grating is replaced with the waveguide array. By setting the difference in the lengths between the shortest waveguide and the longest waveguide to be large, the AWG can utilize a high-order diffraction that cannot be obtained the plane-shaped reflection diffraction grating, so that a spectroscopy with a high resolution can be structured so as to have a size identical to that of a small sized integrated circuit.

[0040] The wavelength monitoring circuit 420 shown in Fig. 5 has a structure that the combination of the wavelength variable filter 412 and the light receiving ele-

ment 413 in the wavelength monitoring circuit 410 of Fig. 3 is replaced by the combination of the AWG 422 and the array PD 423. The characteristics of the optical switch/array PD control circuit 425 for controlling the optical switch 411 and the array PD 423 are made to be different from those of the control circuit 415 of Fig. 3 depending on differences of elements used therein. For example, the wavelength monitoring circuit 410 of Fig. 3 has to output a sawtooth waveform that shows the sweep signal of Fig. 4(b).

[0041] On the contrary, in the case where a self-sweep type array photodetector typified by a CCD is used for the array PD 423 of the wavelength monitoring circuit 420 of Fig. 5, the self-sweep type array photodetector is permitted to perform an operation to output a plurality of clock signals for a charge transfer driving. A phase of each clock signals is shifted from others. In the case where a charge transfer type array PD is not used for the array PD 423 but an array PD for outputting photoelectric conversion signals in parallel is used, a signal for controlling the charge transfer type array PD is not needed to be outputted particularly, a connection line for connecting the control circuit and the array PD may be omitted. However, in this case, a plurality of connection lines corresponding to the number of the PD arrays, which connect the array PD 423 and the wavelength control signal generating circuit 424, are provided so as to output parallel signals directly from the array PD 423 to the wavelength control signal generating circuit 424.

[0042] Next, an operation of the embodiment in which the self-sweep array photodetector typified by the CCD is used for the array PD 423 of Fig. 5 will be described.

[0043] The optical switch 411 switches the connection between the branched optical signal input 12 and the branched optical signal output 13 alternately so as to connect the AWG 422 with either of the branched optical signals 12 and 13. The AWG 422 separates the optical signal inputted thereto into its spectral components. The AWG 422 gives a positional deviation spatially different from others to each of the separated lights depending on the wavelength of the lights, and allows the separated lights to be emitted therefrom. If the light of the branched optical signal input 12 and the light of the branched optical signal output 13 are different in the wavelength from each other, these lights are separated into their spectral components in the AWG 422 and emitted therefrom.

[0044] The charge transfer type array PD 423 receives each of the lights, each being obtained by separating the light into the spectral components by the AWG 422 and emitted therefrom while deviating spatially from others. The array PD 423 converts each of the lights into an electrical sweep signal, and outputs it to the wavelength control signal generating circuit 424. In this embodiment, the sweep cycle of the self-sweep type array PD 423 is made to be synchronous with the switching cycle of the optical switch 411. Specifically, the array PD 423 performs one sweep within a period of the half-cycle

where the optical switch 411 is in connection with the branched optical signal input 12, and the array PD 423 performs subsequent one sweep within a subsequent period of the half-cycle where the optical switch 411 is in connection with the branched optical signal output 13. The wavelength control signal generating circuit 424 calculates the difference between the first time and the second time. The first time is a period from the sweep start to the peak appearance for the photoelectric conversion signal of the array PD 423 for the branched optical signal input 12 and the second time is a period from the sweep start to the peak appearance for the photoelectric conversion signal of the array PD 423 for the branched optical signal output 13. The first time corresponds to t_1 of Fig. 4(c) for explaining the operation of the embodiment using the mechanical sweep type wavelength variable filter of Fig. 3, and the second time corresponds to t_2 of Fig. 4(c). The wavelength control signal generating circuit 424 transmits the wavelength control signal 9 to the light transmitting circuit 6, based on the calculation result.

[0045] Fig. 6 is a diagram showing another embodiment of the wavelength monitoring circuit 4.

[0046] The wavelength monitoring circuit 430 of Fig. 6 uses two sets of combinations, each of which consists of the wavelength variable filter 412 and the light receiving element 413, instead of the wavelength monitoring circuit 410 and the optical switch 411 of Fig. 3. The wavelength monitoring circuit 410 is composed of the two set of the foregoing combinations; the wavelength variable filter control circuit 435 for controlling the wavelength variable filters 412 so as to sweep the wavelengths in synchronization with each other; and the wavelength control signal generating circuit 434 for creating the wavelength control signal 9 from the parallel signals outputted from the two single type light receiving elements 433.

[0047] The branched optical signal input 12 is coupled to one of the wavelength variable filters 412 for exclusively sweeping the input 12 and separating the input 12 into its spectral components and one of the single type light receiving elements 433, and the branched optical signal output 13 is coupled to the other of the wavelength variable filters 412 for exclusively sweeping the output 13 and separating the output 13 into its spectral components and the other of the light receiving elements 433. The photoelectric conversion outputs from the two light receiving elements 433 are in parallel inputted to the wavelength control signal generating circuit 434. The wavelength control signal generating circuit 434 compares the parallel outputs from the two light receiving elements 433, and calculates the difference between the times when each of the peaks appears originating from the difference between the wavelengths. Then, the wavelength control signal generating circuit 434 generates the wavelength control signal 9, and transmits the wavelength control signal 9.

[0048] Next, still another embodiment of the wave-

length monitoring circuit 440 is shown in Fig. 7.

[0049] The wavelength monitoring circuit 440 of Fig. 7 uses two sets of combinations, each of which is composed of the AWG 442 and the array PD 443, instead of the optical switch 411 of Fig. 4. The wavelength monitoring circuit 440 is composed of the foregoing two sets of components; the array PD control circuit 445 for controlling the two array PDs so as to synchronously sweep the wavelengths; and the wavelength control signal generating circuit 444 for creating the wavelength control signal 9 based on the outputs from the two array PDs.

[0050] The branched optical signal input 12 is coupled to one of the AWG 442 for exclusively separating the input 12 into its spectral components and one of the array type PDs 443 for exclusively allowing the optical output from the corresponding AWG to undergo the photoelectric conversion, and the branched optical signal output 13 is coupled to the other of the AWG 442 for exclusively separating the output 13 into its spectral components and one of the array type PDs 443 for exclusively allowing the optical output from the corresponding AWG to undergo the photoelectric conversion. The photoelectric conversion outputs from the two array PDs are in parallel inputted to the wavelength control signal generating circuit 444. The wavelength control signal generating circuit 444 compares the parallel outputs from the two array type PDs 443, and calculates the difference between the times when each of the peaks appears originating from the difference between the wavelengths. Then, the wavelength control signal generating circuit 444 generates the wavelength control signal 9, and transmits the wavelength control signal 9.

[0051] Next, a more concrete embodiment of the light transmitting circuit 6 of Fig. 2 will be described.

[0052] The light transmitting circuit 6 has a function to perform a modulation based on the regenerated electrical signal 14 from the light receiving circuit 5 and to output the light transmitting circuit output light 15; and a function to control the wavelength based on the wavelength control signal 9 outputted from the wavelength monitoring circuit 4. The light transmitting circuit 6 is a light source having a function capable of performing a high speed electrical-to-optical conversion and allowing the wavelength to be variable.

[0053] Fig. 8 is a diagram showing a structure of the light transmitting circuit 610 that is one concrete embodiment of the light transmitting circuit 6.

[0054] The light transmitting circuit 610 is composed of the distributed feedback type LD 601 that is a semiconductor laser device capable of allowing the wavelength to be variable; and the LD driving circuit 602; and the LD temperature control circuit 603 for controlling the temperature of the distributed feedback type LD 601 in order to control the wavelength. The LD driving circuit 602 amplifies the regenerated electrical signal 14 from the light receiving circuit 5 to a signal amplitude so as to be suitable for modulating the wavelength variable semiconductor laser 601, and superposes the regenerated

electrical signal 14 on a bias current suitable for a signal modulation.

[0055] The distributed feedback type LD 601 is called a DFB-LD (Distributed Feedback Laser Diode) for short. As is well known, the DFB-LD, in which its longitudinal (axis) is defined by a reflection due to a Bragg grating cut in the optical guide layer, operates with a single longitudinal mode without depending a facing reflection, and suitable for a high speed communication. At the same time, the DFB-LD exhibits a great change of an oscillation wavelength originating from a change in an index of refraction due to a temperature change. In a crystalline material for forming a semiconductor laser with a wavelength of 1.55 μm , this change in the wavelength is about 3Å per a temperature change of 1°C. This is equivalent to a value ranging from about 30 to 40 GHz that is obtained by converted the wavelength change in terms of a frequency. When a high density wavelength multiplexing optical communication system with a frequency (wavelength) interval of, for example, about 100 GHz is assumed, this suggests that it is possible actually to control the wavelength by controlling the temperature of the semiconductor laser.

[0056] In Fig. 8, based on the wavelength control signal 9 from the wavelength control circuit 4, the LD temperature control circuit 603 controls the oscillation wavelength by the temperature of the distributed feedback type LD 601. Therefore, the thermistor output 605 from the thermistor thermometer for detecting the temperature of the LD, which is provided in the vicinity of the distributed feedback type LD 601. Thus, the Peltier control current 604 for heating and cooling the distributed feedback type LD 601 is outputted.

[0057] A structure of another embodiment of the light transmitting circuit 6 is shown in Fig. 9.

[0058] In Fig. 9, the light transmitting circuit 620 is composed of the distributed reflection type LD 611 that is a device different from the DF-LD of the semiconductor laser capable of allowing the wavelength to be variable; the LD driving circuit 612; and the LD current control circuit 613 for controlling the current of the distributed reflection type LD 611 to control the wavelength.

[0059] The LD driving circuit 612 amplifies the regenerated electrical signal 14 from the light receiving circuit 5 to a signal amplitude that is suitable for modulating the wavelength variable semiconductor laser 611, and superposes a bias current suitable for a signal modulation on the regenerated electrical signal 14.

[0060] The distributed reflection type LD 611 is called a DBR-LD (Distributed Bragg Reflector Laser Diode) for short. The DBR-LD has a structure that an activation region for emitting and amplifying a light, a DBR region for selecting one oscillation mode, and a phase adjusting region for controlling the longitudinal mode wavelength are formed in series in a light travelling direction so as to constitute a resonator against the light. Bias currents injected into the respective regions are individ-

ually set independently from each other, so that electrodes in the three regions are separated. A Bragg diffraction grating is formed in an optical waveguide layer in the DBR region and only a light with a specified wavelength (Bragg wavelength) is strongly reflected. As a result, one longitudinal mode in the vicinity of the Bragg wavelength is an oscillation mode. The Bragg wavelength can be controlled by changing the index of refraction of the waveguide layer by the current injection. The phase adjusting region is the one where the diffraction grating is not formed, and the index of refraction changes by injecting the current into this region. An optical length of the resonator changes due to the change of the index of refraction, so that a fine control for the oscillation wavelength can be performed. A current obtained by superposing the bias current on the regenerated electrical signal 14 is supplied to the electrode of the activation region, by the LD driving circuit 602.

[0061] Experimental confirmation shows an example in which when a current flowing through the Bragg region was allowed to change from 0 to 50 mA, the Bragg wavelength changed greatly by about 70 Å from 1.553 to 1.546 μm.

[0062] In Fig. 9, the LD current control circuit 613 outputs the oscillation wavelength control current 614 that is a current supplied to the DBR region of the distributed reflection type LD 611, which controls the oscillation wavelength of the distributed reflection type LD 611 based on the wavelength control signal 9 from the wavelength control circuit 4, and the phase control current 615 which is supplied to the phase adjusting region and finely controls the oscillation wavelength. The LD current control circuit 613 may be provided with a function to control the temperature of the distributed reflection type LD 611 as required, in addition to the foregoing function.

[0063] Next, the wavelength division multiplexing transmitting system used for the regeneration optical relay apparatus including the regeneration relay 2 of the present invention will be described.

[0064] Fig. 10 is a diagram showing a structure of the wavelength division multiplexing transmitting system using including the regeneration optical relay 2 of the present invention, which is illustrated so as to compared the wavelength division multiplexing transmitting system with the wavelength multiplexing signal transmitting system including the optical regeneration relay. The wavelength division multiplexing transmitting system is composed of an optical transmitting terminal station system 500; an optical amplifying relay system 600; an optical regeneration relay system 700; and a subsequent stage transmitting system 800. The optical regeneration relay system 700 demultiplexes the transmitting signal by the demultiplexer 105, which has been subjected to the wavelength multiplexing. The optical regeneration relay system 700 multiplexes the optical outputs from the optical regeneration relay apparatus

106, which comprises the foregoing regeneration optical relays 6 provided corresponding to the number of the wavelengths, and each of the regeneration optical relays 6 by the multiplexer 108 again, and transmits the multiplexed output to the subsequent transmitting system 800 having the transmission path 109.

[0065] By using the optical regeneration relay apparatus having the regeneration optical relay of the present invention, the wavelength of the optical transmitter in the wavelength division multiplexing transmitting unit 101 of the optical transmitting terminal station system 500 at the first stage of the transmission path is controlled, whereby the wavelength of the whole of the transmission paths can be controlled.

[0066] As described above, the present invention has a feature in that the wavelength of the output signal in the regeneration relay is controlled so as to be equal to the wavelength of the input signal. Since the wavelength variable light source is used for the light source, it is unnecessary to prepare the regeneration optical relay for each of the different wavelengths. By controlling the wavelength of the optical transmitter at the first stage of the transmission path, it will be possible to control the wavelengths of the whole of the transmission path.

[0067] While this invention has been described in connection with certain preferred embodiments, it is to be understood that the subject matter encompassed by way of this invention is not to be limited to those specific embodiments. On the contrary, it is intended for the subject matter of the invention to include all alternative, modification and equivalents as can be included within the spirit and scope of the following claims.

Claims

1. An optical regeneration relay comprising:

a light receiving circuit for converting an optical signal inputted thereto to an electrical signal to output the electrical signal;
a light transmitting circuit for converting the electrical signal outputted from said light receiving circuit to an optical signal, and allowing a wavelength of said optical signal to be variable and outputting said optical signal; and
a wavelength monitoring circuit for controlling said light transmitting circuit so that a wavelength of said optical signal outputted from said light transmitting circuit and is equal to that of said optical signal inputted to said light receiving circuit.

2. The regeneration optical relay according to claim 1, wherein said wavelength monitoring circuit comprises:

an optical switch having two input terminals and one output terminal, which alternately

- switches between a first optical signal input to be referred and a second optical signal input that is the output of said light transmitting circuit, a wavelength of the second optical signal input being controlled;
- a wavelength discriminator for discriminating a wavelength of an output light from the optical switch to convert the output light to an electrical signal, thereby outputting the electrical signal;
- a wavelength control signal generating circuit for calculating a difference between wavelengths of said first and second optical signal inputs based on the electrical signal from said wavelength discriminator, and transmitting a signal for controlling a wavelength to said light transmitting circuit; and
- a control circuit for controlling said optical switch, wavelength discriminator and wavelength control signal generating circuit.
3. The regeneration optical relay according to claim 1 or 2, wherein said wavelength monitoring circuit comprises:
- two sets of wavelength discriminators for discriminating between a wavelength of a first optical signal input to be referred and a wavelength of a second optical signal input that is the output of said light transmitting circuit, the wavelength of a second optical signal input being controlled, and converting the wavelength to an electrical signal, thereby outputting the electrical signal;
- a wavelength control signal generating circuit for calculating a difference between the wavelengths of said first and second optical signal inputs based on the electrical signal from said wavelength discriminator, and transmitting a signal for controlling a wavelength to said light transmitting circuit; and
- a control circuit for controlling said two sets of wavelength discriminators and said wavelength control signal generating circuit.
4. The regeneration optical relay according to claim 2 or 3, wherein each of said wavelength discriminators comprises a wavelength variable filter and a single type light receiving element.
5. The regeneration optical relay according to claim 2 or 3, wherein said each of said wavelength discriminators comprises a spectrometer and an array type light receiving element.
6. The regeneration optical relay according to claim 4, wherein said wavelength variable filter is a sweep type Fabriperot resonator
7. The regeneration optical relay according to claim 4, wherein said wavelength variable filter is a rotary etaron plate.
8. The regeneration optical relay according to claim 4, wherein said wavelength variable filter is an acoustic optical tunable filter.
9. The regeneration optical relay according to claim 5, wherein said spectrometer is an array waveguide diffraction grating.
10. The regeneration optical relay according to claim 5, wherein said array type light receiving element is a self-sweep type array light receiving element.
11. The regeneration optical relay according to claim 5, wherein said array type light receiving element is a parallel-output type array light receiving element.
12. The regeneration optical relay according to any one of claims 1 to 11, wherein said light transmitting circuit comprises:
- a wavelength variable semiconductor laser;
- a semiconductor laser driving circuit for amplifying a regeneration electrical signal from said light transmitting circuit to a signal amplitude suitable for modulating said wavelength variable semiconductor laser, and superposing a bias current on the regeneration electrical signal, the bias current being suitable for a signal modulation; and
- a semiconductor laser temperature control circuit for controlling an oscillation wavelength of said wavelength variable semiconductor laser by either a temperature or a current, based on a signal for controlling a wavelength from said wavelength control signal generating circuit.
13. The regeneration optical relay according to claim 12, wherein said wavelength variable semiconductor laser is a distributed feedback type semiconductor laser.
14. The regeneration optical relay according to claim 12, wherein said wavelength variable semiconductor laser is a distributed reflection type semiconductor laser.
15. A wavelength multiplexing optical transmitting system comprising:
- a demultiplexer provided on a light transmission path connecting a wavelength multiplexing transmitting terminal station unit and a wavelength multiplexing receiving terminal station, said demultiplexer demultiplexing a wavelength

multiplexing signal transmitted from said light transmitting path;

at least one regeneration optical relay unit for regenerating and relaying a plurality of optical signals outputted from said demultiplexer; and a multiplexer for multiplexing the plurality of optical signals with different wavelengths, which are outputted from said regeneration optical relay unit, and transmitting a multiplexed optical signal onto a light transmitting path, wherein said regeneration optical relay unit comprises:

a light receiving circuit for converting a optical signal with a specified wavelength to an electrical signal to output the electrical signal, the optical signal being inputted to said regeneration optical relay unit;

a light transmitting circuit for converting the electrical signal outputted from said light receiving circuit to an optical signal, and variably outputting a wavelength of said optical signal; and

a wavelength monitoring circuit for controlling said light transmitting circuit so that a wavelength outputted from said light transmitting circuit and a wavelength inputted to said light receiving circuit are made to be equal to each other.

16. The wavelength multiplexing optical transmitting system according to claim 15, said wavelength multiplexing transmitting system further comprising:

an optical amplifier arranged on said light transmitting path, said optical amplifier performing an optical amplifying for said optical signal.

17. An optical regeneration relay which comprises a light receiver, a light transmitter and a wavelength monitoring circuit, comprising:

converting an optical signal inputted to said light receiver to an electrical signal, thereby outputting the electrical signal from said light receiver to said light transmitter;

converting the electrical signal to an optical signal by said light transmitter and outputting the optical signal from said light transmitter variably; and

controlling an output wavelength from said light transmitter by said wavelength monitoring circuit so that a wavelength outputted from said light transmitter and a wavelength inputted to said light receiver are made to be equal to each other.
